11 Policy Gradient Estimation

The previous chapter discussed several ways to go about directly optimizing the parameters of a policy to maximize expected utility. In many applications, it is often useful to use the gradient of the utility with respect to the policy parameters to guide the optimization process. This chapter discusses several approaches to estimating this gradient from trajectory rollouts.¹ A major challenge with this approach is the variance of the estimate due to the stochastic nature of the trajectories arising from both the environment and our exploration of it. The next chapter will discuss how to use these algorithms for gradient estimation for the purpose of policy optimization.

11.1 Finite Difference

Finite difference methods estimate the gradient of a function from small changes in its evaluation. Recall that the derivative of a univariate function \( f \) is

\[
\frac{df}{dx}(x) = \lim_{\delta \to 0} \frac{f(x + \delta) - f(x)}{\delta}
\]  \hspace{1cm} (11.1)

The derivative at \( x \) can be approximated by a sufficiently small step \( \delta > 0 \):

\[
\frac{df}{dx}(x) \approx \frac{f(x + \delta) - f(x)}{\delta}
\]  \hspace{1cm} (11.2)

This approximation is illustrated in figure 11.1.

The gradient of a multivariate function \( f \) with an input of length \( n \) is:

\[
\nabla f(x) = \left[ \frac{\partial f}{\partial x_1}(x), \ldots, \frac{\partial f}{\partial x_n}(x) \right]
\]  \hspace{1cm} (11.3)

Finite differences can be applied to each dimension to estimate the gradient.

In the context of policy optimization, we want to estimate the gradient of the utility expected from following a policy parameterized by $\theta$:

$$\nabla U(\theta) = \left[ \frac{\partial U}{\partial \theta_1}(\theta), \ldots, \frac{\partial U}{\partial \theta_n}(\theta) \right]$$

$$\approx \left[ \frac{U(\theta + \delta e^{(1)}) - U(\theta)}{\delta}, \ldots, \frac{U(\theta + \delta e^{(n)}) - U(\theta)}{\delta} \right]$$

(11.4)

(11.5)

where $e^{(i)}$ is the $i$th standard basis vector consisting of zeros except for the $i$th component that is set to 1.

As discussed in section 10.1, we need to simulate policy rollouts to estimate $U(\theta)$. We can use algorithm 11.1 to generate trajectories. From these trajectories, we can compute their return and estimate the utility associated with the policy. Algorithm 11.2 implements the gradient estimate in equation (11.5) by simulating $m$ rollouts for each component and averaging the returns.

A major challenge in arriving at accurate estimates of the policy gradient is the fact that the variance of the trajectory rewards can be quite high. One approach to reduce the resulting variance in the gradient estimate is to have each rollout share the same random generator seeds. This approach can be helpful, for example, in cases where one rollout happens to hit a low-probability transition early on. Other rollouts will have the same tendency due to the shared random generator, and their rewards will tend to be biased in the same way.

Policy representations have a significant effect on the policy gradient. Example 11.1 demonstrates the sensitivity of the policy gradient to the policy parameterization. Finite differences for policy optimization can perform poorly when the parameters differ in scale.

---

**Algorithm 11.1.** A method for generating a trajectory associated with problem $\mathcal{P}$ starting in state $s$ and executing policy $\pi$ to depth $d$. It creates a vector $\tau$ containing state-action-reward tuples.

```
function simulate($\mathcal{P}$::MDP, $s$, $\pi$, $d$)
    $\tau = []$
    for $i = 1:d$
        $a = \pi(s)$
        $s', \tau = \mathcal{P}.TR(s, a)$
        push!(\tau, ($s, a, r$))
        $s = s'$
    end
    return $\tau$
end
```
struct FiniteDifferenceGradient
    ϱ # problem
    b # initial state distribution
    d # depth
    m # number of samples
    δ # step size
end

function gradient(M::FiniteDifferenceGradient, π, θ)
    ϱ, b, d, m, δ, γ, n = M.ϱ, M.b, M.d, M.m, M.δ, M.ϱ.γ, length(θ)
    Δθ(i) = [i == k ? δ : 0.0 for k in 1:n]
    R(τ) = sum(ᵣ⁺ γ⁺(k-1) for (k, (s,a,ᵣ)) in enumerate(τ))
    U(θ) = mean(R(simulate(ϱ, rand(b), s→π(θ, s), d)) for i in 1:m)
    ΔU = [U(θ + Δθ(i)) - U(θ) for i in 1:n]
    return ΔU ./ δ
end

Consider a single-state, single-step MDP with a one-dimensional continuous action space and a reward function \( R(s,a) = a \). In this case, larger actions produce higher rewards.

Suppose we have a stochastic policy \( π_θ \) that samples its action according to a uniform distribution between \( θ_1 \) and \( θ_2 \) for \( θ_2 > θ_1 \). The expected value is:

\[
U(θ) = \mathbb{E}[a] = \int_{θ_1}^{θ_2} a \frac{1}{θ_2 - θ_1} \, da = \frac{θ_1 + θ_2}{2}
\]

The policy gradient is:

\[
\nabla U(θ) = [1/2, 1/2]
\]

The policy could be reparameterized to draw actions from a uniform distribution between \( θ_1 \) and \( 100θ_2 \), for \( 100θ_2 > θ_1 \). Now the expected reward is \( (θ_1 + 100θ_2)/2 \) and the policy gradient is \([1/2, 50]\).

Both policies are identical from the agent’s perspective, but the two have wildly different gradients. Finding a suitable perturbation scalar for the second policy is much more difficult, as the parameters vary widely in scale.
11.2 Regression Gradient

Instead of estimating the gradient at $\theta$ by taking a fixed step along each coordinate axis as done in the previous section, we can use linear regression\(^3\) to estimate the gradient from the results of random perturbations from $\theta$. These perturbations are stored in a matrix:

$$\Delta \Theta = \begin{bmatrix} (\Delta \theta^{(1)})^\top \\ \vdots \\ (\Delta \theta^{(m)})^\top \end{bmatrix}$$ (11.6)

More policy parameter perturbations will tend to produce better gradient estimates.\(^4\)

For each of these perturbations, we perform a rollout and estimate the change in utility:\(^5\)

$$\Delta U = \begin{bmatrix} U(\theta + \Delta \theta^{(1)}) - U(\theta), \ldots, U(\theta + \Delta \theta^{(m)}) - U(\theta) \end{bmatrix}$$ (11.7)

The policy gradient estimate using linear regression is then:\(^6\)

$$\nabla U(\theta) \approx \Delta \Theta^+ \Delta U$$ (11.8)

Algorithm 11.3 provides an implementation of this approach where the perturbations are drawn uniformly from a hypersphere with radius $\delta$. Example 11.2 demonstrates this approach on a simple function.

```
struct RegressionGradient
    # problem
    P # problem
    # initial state distribution
    b # initial state distribution
    # depth
    d # depth
    # number of samples
    m # number of samples
    # step size
    δ # step size
end

function gradient(M::RegressionGradient, π, θ)
    P, b, d, m, δ, γ = M.P, M.b, M.d, M.m, M.δ, M.γ
    Δθ = [δ.*normalize(randn(length(θ)), 2) for i = 1:m]
    R(τ) = sum(r*y^(k-1) for (k, (s,a,r)) in enumerate(τ))
    U(θ) = R(simulate(P, rand(b), s->π(θ,s), d))
    ΔU = [U(θ + Δθ) - U(θ) for Δθ in Δθ]
    return pinv(reduce(hcat, Δθ)^\top) * ΔU
end
```

Algorithm 11.3. A method for estimating a policy gradient using finite differences for an MDP $\mathcal{P}$, a stochastic parameterized policy $\pi(\theta, s)$, and policy parameterization vector $\theta$. Policy variation vectors are generated by normalizing normally-distributed samples and scaling by a perturbation scalar $\delta$. A total of $m$ parameter perturbations are generated, and each is evaluated in a rollout from an initial state drawn from $b$ to depth $d$ and compared to the original policy parameterization.

\(^3\) Linear regression is covered in section 8.6.

\(^4\) A recommended rule of thumb is to use about twice as many perturbations as the number of parameters.

\(^5\) This equation shows the forward difference. Other finite difference formulations, such as the central difference, can also be used.

\(^6\) As discussed earlier in section 8.6, $X^+$ denotes the pseudoinverse of $X$.

We would like to apply the regression gradient to estimate the gradient of a simple one-dimensional function \( f(x) = x^2 \) evaluated at \( x_0 = 2 \) from \( m = 20 \) samples. To imitate the stochasticity inherent in policy evaluation, we add noise to the function evaluations. We generate a set of disturbances \( \Delta X \) sampled from \( \mathcal{N}(0, \delta^2) \) and evaluate \( f(x_0 + \Delta x) - f(x_0) \) for each disturbance \( \Delta x \) in \( \Delta X \). We can then estimate the one-dimensional gradient (or derivative) \( \Delta X^+ \Delta F \) with this code:

\[
f(x) = x^2 + 1e-2 * \text{randn()}
\]
\[
m = 20
\]
\[
\delta = 1e-2
\]
\[
\Delta X = [\delta * \text{randn()} \text{ for } i = 1:m]
\]
\[
x_0 = 2.0
\]
\[
\Delta F = [f(x_0 + \Delta x) - f(x_0) \text{ for } \Delta x \text{ in } \Delta X]
\]
\[
pinv(\Delta X) * \Delta F
\]

The samples and linear regression are shown below. The slope of the regression line is close to the exact solution of 4.

Example 11.2. Demonstration of the regression gradient method on a one-dimensional function.
11.3 Likelihood Ratio

The likelihood ratio approach\(^7\) to gradient estimation uses an analytical form of \(\nabla \pi_\theta\) to improve our estimate of \(\nabla U(\theta)\). Recall from equation (10.2) that

\[
U(\theta) = \int p_\theta(\tau) R(\tau) \, d\tau
\]  
(11.9)

Hence,

\[
\nabla U(\theta) = \nabla_\theta \int p_\theta(\tau) R(\tau) \, d\tau
\]  
(11.10)

\[
= \int \nabla_\theta p_\theta(\tau) R(\tau) \, d\tau
\]  
(11.11)

\[
= \int p_\theta(\tau) \frac{\nabla_\theta p_\theta(\tau)}{p_\theta(\tau)} R(\tau) \, d\tau
\]  
(11.12)

\[
= \mathbb{E}_\tau \left[ \frac{\nabla_\theta p_\theta(\tau)}{p_\theta(\tau)} R(\tau) \right]
\]  
(11.13)

Applying the log derivative trick,\(^8\) we have

\[
\nabla U(\theta) = \mathbb{E}_\tau [\nabla_\theta \log p_\theta(\tau) R(\tau)]
\]  
(11.14)

We can estimate the expectation above using trajectory rollouts. For each trajectory sample \(\tau^{(i)}\), we need to compute the product \(\nabla_\theta \log p_\theta(\tau^{(i)}) R(\tau^{(i)})\). Recall that \(R(\tau^{(i)})\) is the return associated with trajectory \(\tau^{(i)}\). If we have a stochastic policy, the gradient \(\nabla_\theta \log p_\theta(\tau^{(i)})\) is

\[
\nabla_\theta \log p_\theta(\tau) = \sum_{k=1}^d \nabla_\theta \log \pi_\theta(a^{(k)} \mid s^{(k)})
\]  
(11.15)

because \(p_\theta(\tau)\) has the form:

\[
p_\theta(\tau) = p(s^{(1)}) \prod_{k=1}^d T(s^{(k+1)} \mid s^{(k)}, a^{(k)}) \pi_\theta(a^{(k)} \mid s^{(k)})
\]  
(11.16)

where \(s^{(k)}\) and \(a^{(k)}\) are the \(k\)th state and action, respectively, in trajectory \(\tau\). Algorithm 11.4 provides an implementation where \(m\) trajectories are sampled to arrive at a gradient estimate. Example 11.3 illustrates the process.
If we have a deterministic policy, the gradient requires computing:

\[ \nabla_{\theta} \log p_{\theta}(\tau) = \nabla_{\theta} \log \left[ p(s^{(1)}) \prod_{k=1}^{d} T(s^{(k+1)} \mid s^{(k)}, \pi_{\theta}(s^{(k)})) \right] \]

\[ = \sum_{k=1}^{d} \nabla_{\theta} \pi_{\theta}(s^{(k)}) \frac{\partial}{\partial a^{(k)}} \log T(s^{(k+1)} \mid s^{(k)}, a^{(k)}) \]  

The equation above requires knowing the transition likelihood, which is in contrast with equation (11.15) for stochastic policies.

Algorithm 11.4. A method for estimating a policy gradient of a policy \( \pi(s) \) for an MDP \( \mathcal{P} \) with initial state distribution \( b \) using the likelihood ratio trick. The gradient with respect to the parameterization vector \( \theta \) is estimated from \( m \) rollouts to depth \( d \) using the log policy gradients \( \nabla \log \pi \).

11.4 Reward-to-Go

The likelihood ratio policy gradient method is unbiased but has high variance. Example 11.4 reviews bias and variance. The variance generally increases significantly with rollout depth due to the correlation between actions, states, and rewards across time steps. The reward-to-go approach attempts to reduce the variance in the estimate.

To derive this approach, we begin by expanding equation (11.14):

\[ \nabla U(\theta) = \mathbb{E}_{\tau} \left[ \left( \sum_{k=1}^{d} \nabla_{\theta} \log \pi_{\theta}(a^{(k)} \mid s^{(k)}) \right) \left( \sum_{k=1}^{d} r^{(k)} \gamma^{k-1} \right) \right] \]

Let \( f^{(k)} \) replace \( \nabla_{\theta} \log \pi_{\theta}(a^{(k)} \mid s^{(k)}) \) for convenience. We then expand:

\[ \nabla_{\theta} U(\theta) = \mathbb{E}_{\tau} \left[ \sum_{k=1}^{d} f^{(k)} \gamma^{k-1} \right] \]
Consider the single-step, single-state problem from example 11.1. Suppose we have a stochastic policy $\pi_\theta$ that samples its action according to a Gaussian distribution $\mathcal{N}(\theta_1, \theta_2^2)$ where $\theta_2^2$ is the variance.

The log policy likelihood is:

$$
\log \pi_\theta(a | s) = \log \left( \frac{1}{\sqrt{2\pi\theta_2^2}} \exp \left( -\frac{(a - \theta_1)^2}{2\theta_2^2} \right) \right)
$$

$$
= -\frac{(a - \theta_1)^2}{2\theta_2^2} - \frac{1}{2} \log(2\pi\theta_2^2)
$$

The gradient of the log policy likelihood is:

$$
\frac{\partial}{\partial \theta_1} \log \pi_\theta(a | s) = \frac{a - \theta_1}{\theta_2^2}
$$

$$
\frac{\partial}{\partial \theta_2} \log \pi_\theta(a | s) = \frac{(a - \theta_1)^2 - \theta_2^2}{\theta_2^3}
$$

Suppose we run three rollouts with $\theta = [0, 1]$, taking actions $\{0.5, -1, 0.7\}$ and receiving the same rewards $(R(s, a) = a)$. The estimated policy gradient is:

$$
\nabla U(\theta) \approx \frac{1}{m} \sum_{i=1}^{m} \nabla \theta \log p_\theta(\tau^{(i)}) R(\tau^{(i)})
$$

$$
= \frac{1}{3} \left( \begin{bmatrix} 0.5 \\ -0.75 \end{bmatrix} \cdot 0.5 + \begin{bmatrix} -1.0 \\ 0.0 \end{bmatrix} \cdot (-1) + \begin{bmatrix} 0.7 \\ -0.51 \end{bmatrix} \cdot 0.7 \right)
$$

$$
= [0.58, -0.244]
$$
When estimating a quantity of interest from a collection of simulations, we generally want to use a scheme that has both low bias and low variance. In this chapter, we want to estimate \( \nabla U(\theta) \). Generally, with more simulation samples, we can arrive at a better estimate. Some methods can lead to bias, where—even with infinitely many samples—it does not lead to an accurate estimate. Sometimes methods with non-zero bias may still be attractive if they have low variance, meaning they require fewer samples to converge.

Below are plots of the estimates from four notional methods for estimating \( \nabla U(\theta) \). The true value is 17.5, as indicated by the red line. We ran 100 simulations 100 times for each method. The variance decreases as the number of samples increases. The blue regions indicate the 5% to 95% and 25% to 75% empirical quantiles of the estimates.

Example 11.4. Empirical demonstration of bias and variance when estimating \( \nabla U(\theta) \).
\[ \nabla U(\theta) = \mathbb{E}_\tau \left[ \left( \sum_{k=1}^{d} f^{(k)} \right) \left( \sum_{k=1}^{d} r^{(k)} \gamma^{k-1} \right) \right] \]

\[ = \mathbb{E}_\tau \left[ \left( f^{(1)} + f^{(2)} + f^{(3)} + \ldots + f^{(d)} \right) \left( r^{(1)} + r^{(2)} \gamma + r^{(3)} \gamma^2 + \ldots + r^{(d)} \gamma^{d-1} \right) \right] \]

\[ = \mathbb{E}_\tau \left[ \begin{array}{l}
  f^{(1)} r^{(1)} + f^{(1)} r^{(2)} \gamma + f^{(1)} r^{(3)} \gamma^2 + \ldots + f^{(1)} r^{(d)} \gamma^{d-1} \\
  + f^{(2)} r^{(1)} + f^{(2)} r^{(2)} \gamma + f^{(2)} r^{(3)} \gamma^2 + \ldots + f^{(2)} r^{(d)} \gamma^{d-1} \\
  + f^{(3)} r^{(1)} + f^{(3)} r^{(2)} \gamma + f^{(3)} r^{(3)} \gamma^2 + \ldots + f^{(3)} r^{(d)} \gamma^{d-1} \\
  \vdots \\
  + f^{(d)} r^{(1)} + f^{(d)} r^{(2)} \gamma + f^{(d)} r^{(3)} \gamma^2 + \ldots + f^{(d)} r^{(d)} \gamma^{d-1} 
\end{array} \right] \]

(11.20)

(11.21)

(11.22)

The first reward, \( r^{(1)} \), is only affected by the first action. Thus, its contribution to the policy gradient should not depend on subsequent timesteps. We can remove other such causality-violating terms:\(^{10}\)

\[ \nabla U(\theta) = \mathbb{E}_\tau \left[ \begin{array}{l}
  f^{(1)} r^{(1)} + f^{(1)} r^{(2)} \gamma + f^{(1)} r^{(3)} \gamma^2 + \ldots + f^{(1)} r^{(d)} \gamma^{d-1} \\
  + f^{(2)} r^{(2)} \gamma + f^{(2)} r^{(3)} \gamma^2 + \ldots + f^{(2)} r^{(d)} \gamma^{d-1} \\
  + f^{(3)} r^{(3)} \gamma^2 + \ldots + f^{(3)} r^{(d)} \gamma^{d-1} \\
  \vdots \\
  + f^{(d)} r^{(d)} \gamma^{d-1} 
\end{array} \right] \]

(11.23)

(11.24)

(11.25)

(11.26)

Algorithm 11.5 provides an implementation.

Notice that the reward-to-go for a state-action pair \((s, a)\) under a policy parameterized by \(\theta\) is really an approximation of the state-action value from that state, \(Q_\theta(s, a)\). The action value function, if known, can be used to obtain the policy gradient:

\[ \nabla U(\theta) = \mathbb{E}_\tau \left[ \sum_{k=1}^{d} \nabla \log \pi_\theta(a^{(k)} \mid s^{(k)}) \left( \sum_{\ell=k}^{d} r^{(\ell)} \gamma^{\ell-1} \right) \right] \]

(11.27)

\(^{10}\) The term \( \sum_{\ell=k}^{d} r^{(\ell)} \gamma^{\ell-k} \) is often called the reward-to-go from step \(k\).
11.5 Baseline Subtraction

We can further build on the approach presented in the previous section by sub-
tracting a baseline value from the reward-to-go to reduce the variance of the
gradient estimate. This subtraction does not bias the gradient.

We begin by converting the expectation into nested expectations, as illustrated
in figure 11.2:

\[
\mathbb{E}_\tau \left[ \nabla_\theta \log \pi_\theta(a^{(k)} | s^{(k)}) \gamma^{k-1} r^{(k)}_{\text{to-go}} - r^{(k)}_{\text{base}}(s^{(k)}) \right] \quad (11.28)
\]

To show that baseline subtraction does not bias the gradient, we first expand:

\[
\mathbb{E}_\tau \left[ \sum_{k=1}^{d} \nabla_\theta \log \pi_\theta(a^{(k)} | s^{(k)}) \gamma^{k-1} r^{(k)}_{\text{to-go}} - \sum_{k=1}^{d} \nabla_\theta \log \pi_\theta(a^{(k)} | s^{(k)}) \gamma^{k-1} r^{(k)}_{\text{base}}(s^{(k)}) \right] 
= \mathbb{E}_\tau \left[ \nabla_\theta \log \pi_\theta(a^{(k)} | s^{(k)}) \gamma^{k-1} r^{(k)}_{\text{base}}(s^{(k)}) \right] \quad (11.29)
\]

We could also subtract a baseline from a state-action value.

The linearity of expectation states that \( \mathbb{E}[a + b] = \mathbb{E}[a] + \mathbb{E}[b] \), so it is sufficient
to prove that equation (11.29) is equivalent to equation (11.26), if for each step \( k \),
the expected associated baseline term is 0:

\[
\mathbb{E}_\tau \left[ \nabla_\theta \log \pi_\theta(a^{(k)} | s^{(k)}) \gamma^{k-1} r^{(k)}_{\text{base}}(s^{(k)}) \right] = 0 \quad (11.30)
\]

We begin by converting the expectation into nested expectations, as illustrated
in figure 11.2:

\[
\mathbb{E}_{\tau_{k+1:d}} \left[ \nabla_\theta \log \pi_\theta(a^{(k)} | s^{(k)}) \gamma^{k-1} r^{(k)}_{\text{base}}(s^{(k)}) \right] = \mathbb{E}_{\tau_{k+1:d}} \left[ \nabla_\theta \log \pi_\theta(a^{(k)} | s^{(k)}) \gamma^{k-1} r^{(k)}_{\text{base}}(s^{(k)}) \right] \quad (11.31)
\]
Therefore, subtracting a term \( r \) down the equations in our derivation, we define

\[
\ell_i(a, s, k) = \gamma^{k-1} \frac{\partial}{\partial \theta_i} \log \pi_{\theta}(a | s)
\]  

Figure 11.2. The expectation of a function of trajectories sampled from a policy can be viewed as an expectation over a nested expectation of sub-trajectories. For a mathematical derivation, see exercise 11.3.

We continue with our derivation, using the same log derivative trick that was used in section 11.3:

\[
\mathbb{E}_{\tau_{1:k}} \left[ \mathbb{E}_{\tau_{k+1:d}} \left[ \nabla_{\theta} \log \pi_{\theta}(a^{(k)} | s^{(k)}) \gamma^{k-1} r_{base}(s^{(k)}) \right] \right]
\]

\[
= \mathbb{E}_{\tau_{1:k}} \left[ \gamma^{k-1} r_{base}(s^{(k)}) \mathbb{E}_{\tau_{k+1:d}} \left[ \nabla_{\theta} \log \pi_{\theta}(a^{(k)} | s^{(k)}) \right] \right]
\]

\[
= \mathbb{E}_{\tau_{1:k}} \left[ \gamma^{k-1} r_{base}(s^{(k)}) \mathbb{E}_{a^{(k)}} \left[ \nabla_{\theta} \log \pi_{\theta}(a^{(k)} | s^{(k)}) \right] \right]
\]

\[
= \mathbb{E}_{\tau_{1:k}} \left[ \gamma^{k-1} r_{base}(s^{(k)}) \int \nabla_{\theta} \log \pi_{\theta}(a^{(k)} | s^{(k)}) \pi_{\theta}(a^{(k)} | s^{(k)}) da^{(k)} \right]
\]

\[
= \mathbb{E}_{\tau_{1:k}} \left[ \gamma^{k-1} r_{base}(s^{(k)}) \nabla_{\theta} \int \pi_{\theta}(a^{(k)} | s^{(k)}) da^{(k)} \right]
\]

\[
= \mathbb{E}_{\tau_{1:k}} \left[ \gamma^{k-1} r_{base}(s^{(k)}) \nabla_{\theta} 1 \right]
\]

\[
= \mathbb{E}_{\tau_{1:k}} \left[ \gamma^{k-1} r_{base}(s^{(k)}) 0 \right]
\]

Therefore, subtracting a term \( r_{base}(s^{(k)}) \) does not bias the estimate. This derivation assumed continuous state and action spaces. The same result applies to discrete spaces.

We can choose a different \( r_{base}(s) \) for every component of the gradient, and will select them to minimize the variance. For simplicity, we will drop the dependence on \( s \) and treat each baseline component as constant.\footnote{Some methods approximate a state-dependent baseline using \( r_{base}(s^{(k)}) = \Phi(s^{(k)})^\top w \). Selecting appropriate baseline functions tends to be difficult. J. Peters and S. Schaal, “Reinforcement Learning of Motor Skills with Policy Gradients,” Neural Networks, vol. 21, no. 4, pp. 682–697, 2008.} For compactness in writing down the equations in our derivation, we define

\[
\ell_i(a, s, k) = \gamma^{k-1} \frac{\partial}{\partial \theta_i} \log \pi_{\theta}(a | s)
\]   

\(236\) CHAPTER 11. POLICY GRADIENT ESTIMATION
The variance of the $i$th component of our gradient estimate in equation (11.28) is

$$E_{a,s,r_{to-go},k} \left[ \left( \ell_i (a, s, k) (r_{to-go} - r_{base,i}) \right)^2 \right] - E_{a,s,r_{to-go},k} \left[ \ell_i (a, s, k) (r_{to-go} - r_{base,i}) \right]^2$$

(11.40)

where the expectation is over the $(a, s, r_{to-go})$ tuples in our trajectory samples, and $k$ is each tuple’s depth.

We have just shown that the second term is zero. Hence, we can focus on choosing $r_{base,i}$ to minimize the first term by taking the derivative with respect to the baseline and setting it to zero:

$$\frac{\partial}{\partial r_{base,i}} E_{a,s,r_{to-go},k} \left[ \left( \ell_i (a, s, k) (r_{to-go} - r_{base,i}) \right)^2 \right]$$

$$= \frac{\partial}{\partial r_{base,i}} \left( E_{a,s,r_{to-go},k} \left[ \ell_i (a, s, k)^2 r_{to-go} \right] - 2 E_{a,s,r_{to-go},k} \left[ \ell_i (a, s, k)^2 r_{to-go} r_{base,i} \right] + r_{base,i}^2 E_{a,s,k} \left[ \ell_i (a, s, k)^2 \right] \right)$$

(11.41)

$$= -2 E_{a,s,r_{to-go},k} \left[ \ell_i (a, s, k)^2 r_{to-go} \right] + 2 r_{base,i} E_{a,s,k} \left[ \ell_i (a, s, k)^2 \right] = 0$$

(11.42)

Solving for $r_{base,i}$ yields the baseline component that minimizes the variance:

$$r_{base,i} = \frac{E_{a,s,r_{to-go},k} \left[ \ell_i (a, s, k)^2 r_{to-go} \right]}{E_{a,s,k} \left[ \ell_i (a, s, k)^2 \right]}$$

(11.43)

It is common to use likelihood ratio policy gradient estimation with this baseline subtraction (algorithm 11.6).\textsuperscript{13} Figure 11.3 compares the methods we discussed.

Qualitatively, when considering the gradient contribution of state-action pairs, what we really care about is the relative value of one action over another. If all actions in a particular state produce the same high value, there is no real signal in the gradient, and baseline subtraction can zero that out. We want to identify the actions that produce a higher value than others, irrespective of what the mean value is across actions.

An alternative to the action value is the advantage, $A(s, a) = Q(s, a) - U(s)$. Using the state value function in baseline subtraction produces the advantage. The policy gradient using the advantage is unbiased and typically has much lower
Algorithm 11.6. Likelihood ratio gradient estimation with reward-to-go and baseline subtraction for an MDP $\mathcal{P}$, policy $\pi$, and initial state distribution $b$. The gradient with respect to the parameterization vector $\theta$ is estimated from $m$ rollouts to depth $d$ using the log policy gradients $\nabla \log \pi$.

Figure 11.3. Several policy gradient methods used to optimize policies for the simple regulator problem from the same initial parameterization. Each gradient evaluation ran 6 rollouts to depth 10. The magnitude of the gradient was limited to 1 and step updates were applied with a step size 0.2. The optimal policy parameterization is shown in black.
11.6 Summary

- A gradient can be estimated using finite-differences.
- Linear regression can also be used to provide more robust estimates of the policy gradient.
- The policy gradient theorem can be used to derive a form of the policy gradient that separates the gradient of the action likelihood, which can typically be computed.
- The variance of the policy gradient can be significantly reduced using the reward-to-go and baseline subtraction.

11.7 Exercises

Exercise 11.1. If we estimate the expected discounted return of a given parameterized policy \( \pi_\theta \) defined by an \( n \)-dimensional vector of parameters \( \theta \) using \( m \) rollouts, how many total rollouts do we need to perform to compute the policy gradient using a finite difference approach?

Solution: In order to estimate the policy gradient using a finite difference approach, we need to estimate the utility of the policy given the current parameter vector \( U(\theta) \) as well as given all \( n \) variations of the current parameter vector \( U(\theta + \delta e^{(i)}) \) for \( i = 1 : n \). Since we estimate each of these using \( m \) rollouts, we need to perform a total of \( m(n + 1) \) rollouts.

Exercise 11.2. Consider policy gradients of the form:

\[
\nabla_\theta R(\pi) = E_\tau \left[ \sum_{k=1}^{d} \nabla_\theta \log \pi_\theta(a^{(k)} \mid s^{(k)}) \gamma^{k-1} A_\theta(s^{(k)}, a^{(k)}) \right]
\]

Which of the following values of \( y \) result in a valid policy gradient?

(a) \( \gamma^{1-k} \sum_{\ell=1}^{\infty} r^{(\ell)} \gamma^{\ell-1} \)
(b) $\sum_{\ell=k}^{\infty} r(\ell) \gamma^{\ell-k}$

(c) $\left(\sum_{\ell=k}^{\infty} r(\ell) \gamma^{\ell-k}\right) - r_{\text{base}}(s^{(k)})$

(d) $U(s^{(k)})$

(e) $Q(s^{(k)}, a^{(k)})$

(f) $A(s^{(k)}, a^{(k)})$

(g) $r^{(k)} + \gamma U(s^{(k+1)}) - U(s^{(k)})$

**Solution:**

(a) $\sum_{\ell=1}^{\infty} r(\ell)$ results in the total discounted reward, as

$$\gamma^{k-1} \gamma^{1-k} \sum_{\ell=1}^{\infty} r(\ell) \gamma^{\ell-1} = \sum_{\ell=1}^{\infty} r(\ell) \gamma^{\ell-1}$$

and produces a valid policy gradient as given in equation (11.19).

(b) $\sum_{\ell=k}^{\infty} r(\ell) \gamma^{\ell-k}$ is the reward-to-go, and produces a valid policy gradient as given in equation (11.26).

(c) $\left(\sum_{\ell=k}^{\infty} r(\ell)\right) - b(s^{(k)})$ is the baseline subtracted reward-to-go, and produces a valid policy gradient as given in equation (11.28).

(d) $U(s^{(k)})$ is the state value function, and does not produce a valid policy gradient.

(e) $Q(s^{(k)}, a^{(k)})$ is the state-action value function, and produces a valid policy gradient as given in equation (11.27).

(f) $A(s^{(k)}, a^{(k)})$ is the advantage function, and produces a valid policy gradient as given in equation (11.44).

(g) $r^{(k)} + \gamma U(s^{(k+1)}) - U(s^{(k)})$ is the temporal difference residual, and produces a valid policy gradient because it is an unbiased approximation to the advantage function.

**Exercise 11.3.** Show that $\mathbb{E}_{\tau \sim \pi}[f(\tau)] = \mathbb{E}_{\tau_{1:k} \sim \pi}[\mathbb{E}_{\tau_{k+1} \sim \pi}[f(\tau)]]$ for some step $k$.

**Solution:** The nested expectations can be proven by writing the expectation in integral form and then converting back:
Exercise 11.4. Our implementation of the regression gradient (algorithm 11.3) fits a linear mapping from perturbations to the difference in returns, $U(\theta + \Delta \theta^{(i)}) - U(\theta)$. We evaluate $U(\theta + \Delta \theta^{(i)})$ and $U(\theta)$ for each of the $m$ perturbations, thus re-evaluating $U(\theta)$ a total of $m$ times. How might we reallocate the samples in a more effective manner?

Solution: One approach is to evaluate $U(\theta)$ once and use the same value for each perturbation, thereby conducting only $m + 1$ evaluations. Having an accurate estimate of $U(\theta)$ is particularly important for an accurate regression gradient estimate. An alternative is to still compute $U(\theta)$ once, but use $m$ rollouts, thus preserving the total number of rollouts per iteration. This approach uses the same amount of computation as algorithm 11.3, but it can produce a more reliable gradient estimate.
